Abstract

We are developing a cross-media information retrieval system, in which users can view specific segments of lecture videos by submitting text queries. To produce a text index, the audio track is extracted from a lecture video and a transcription is generated by automatic speech recognition. In this paper, to improve the quality of our retrieval system, we extensively investigate the effects of adapting acoustic and language models on speech recognition. We perform an MLLR-based method to adapt an acoustic model. To obtain a corpus for language model adaptation, we use the textbook for a target lecture to search a Web collection for the pages associated with the lecture topic. We show the effectiveness of our method by means of experiments.

1. Introduction

Given the growing number of multimedia contents available via the World Wide Web and DVDs, retrieving specific information relevant to user needs has become crucial. Because text is one of the most common and effective methods to represent user needs, we proposed a cross-media information retrieval (CMIR) system [1], in which a user can submit text queries to search an entire lecture video program for the relevant segments.

Because oral presentations are usually organized based on text materials, such as textbooks, a user first selects text segments (e.g., keywords, phrases, sentences, and paragraphs) in a textbook related to a target lecture. Then, a text query is generated automatically from one or more selected segments. That is, queries can be formulated even if the user cannot provide effective keywords. The user can also submit additional keywords as queries, if necessary. Finally, video segments are retrieved and presented to the user.

To retrieve video passages in response to text queries, we extract the audio track from a lecture video, generate a transcription by means of automatic speech recognition (ASR), and produce a text index, prior to system use.

In our previous work [1], we proposed a method to adapt a language model for ASR to the topic of a target

lecture. We showed that our method improved the accuracy of ASR and also improved the accuracy of CMIR significantly, by means of experiments.

However, in the previous experiment the vocabulary size was limited to 20K, although a larger vocabulary size, such as 100K, has been used in recent research. In addition, the contribution of acoustic model adaptation on ASR has not been investigated. It may be argued that the effects of adapting models are overshadowed by increasing the vocabulary size. To answer this question, in this paper we extensively investigate the effects of adapting the language and acoustic models on ASR.

2. Cross-media Retrieval System

2.1. Overview

Figure 1 depicts the overall design of our CMIR system, in which the left and right regions correspond to the on-line and off-line processes, respectively. While our system is currently implemented for Japanese, our methodology is fundamentally language independent. For the purpose of research and development, we tentatively target lecture programs on TV for which textbooks are published. We explain the basis of our system using Figure 1.

In the off-line process, given the video data of a target lecture, audio data are extracted and divided into a number of segments. Then, a speech recognition system transcribes each segment. Finally, the transcribed segments are indexed as in conventional text retrieval systems, so that each segment can be retrieved efficiently in response to text queries.

For speech recognition, we use two adaptation methods. To adapt speech recognition to a specific lecturer, we perform unsupervised speaker adaptation using an initial speech recognition result (i.e., a transcription). To adapt speech recognition to a specific topic, we perform language model adaptation, for which we search a large corpus for the documents associated with the textbook for a target lecture. Then, the retrieved documents (i.e., a topic-specific corpus) are used to produce a word-based N-gram language model.

We also perform image analysis to extract text (e.g.,

keywords and phrases) from flip charts. These contents are also used to improve our language model. However, this method is beyond the scope of this paper.

In the on-line process, a user can view specific video segments by submitting any text queries, i.e., keywords, phrases, sentences, and paragraphs, extracted from the textbook. Any queries not in the textbook can also be used. The current implementation is based on a client-server system on the Web. Both the off-line and on-line processes are performed on servers, but users can access our system using Web browsers on their own PCs.

It should be noted that unlike conventional keyword-based retrieval systems, in which users usually submit a small number of keywords, in our system users can easily submit longer queries relying on textbooks. If submitted keywords are misrecognized in transcriptions, the retrieval accuracy decreases. However, long queries are robust for speech recognition errors, because the effect of misrecognized words is overshadowed by the large number of words correctly recognized.

Because our focus in this paper is to investigate the accuracy of speech recognition, in the following sections we elaborate only on speech recognition and document retrieval used to obtain topic-specific corpora.

Figure 1: Overview of our CMIR system.

2.2. Speech Recognition

The speech recognition module generates word sequence W , given phone sequence X . In a stochastic framework, the task is to select the W maximizing $P(W|X)$, which is transformed as in Equation (1) through the Bayesian theorem.

$$\arg \max_W P(W|X) = \arg \max_W P(X|W) \cdot P(W) \quad (1)$$

$P(X|W)$ models the probability that the word sequence W is transformed into the phone sequence X , and $P(W)$ models the probability that W is linguistically acceptable. These factors are called the acoustic and language models, respectively.

We use the Japanese dictation toolkit¹, which includes the Julius decoder and acoustic/language models. Julius performs a two-pass (forward-backward) search using word-based forward bigrams and backward trigrams. The acoustic model was produced from the ASJ speech database, which contains approximately 20,000 sentences uttered by 132 speakers including both gender groups. A 16-mixture Gaussian distribution tri-phone Hidden Markov Model, in which states are clustered into 2,000 groups by a state-tying method, is used. We adapt the provided acoustic model by means of an MLLR-based unsupervised speaker adaptation method, for which we use the HTK toolkit².

Existing methods to adapt language models can be classified into two categories. In the first category—the *integration* approach—general and topic-specific corpora are integrated to produce a language model [2, 3]. Because the sizes of those corpora differ, N-gram statistics are calculated using the weighted average of the statistics extracted independently from those corpora. However, it is difficult to determine the optimal weight depending on the topic. In the second category—the *selection* approach—a topic-specific subset is selected from a general corpus and is used to produce a language model. This approach is effective if a general corpus contains documents associated with a target topic, but the N-gram statistics in those documents are overshadowed by the other documents in the resultant language model.

We followed the selection approach, because the 10M Web page corpus [4] containing mainly Japanese pages associated with various topics was publicly available. In practice, we performed a preprocessing to discard extraneous pages, such as pages including only word lists and script codes. The resultant corpus consists of 7M pages.

The quality of the selection approach depends on the method of selecting topic-specific subsets. An existing method [5] uses hypotheses in the initial speech recognition phase as a query to retrieve topic-specific documents from a general corpus. However, errors in the initial hypotheses have the potential to decrease the retrieval accuracy. Thus, we use the textbook related to a target lecture as a query to improve the retrieval accuracy and consequently the quality of the language model adaptation.

2.3. Document Retrieval

We use an existing probabilistic text retrieval method [6] to compute the relevance score between the query, which is the textbook for a target lecture, and each document in

¹<http://winnie.kuis.kyoto-u.ac.jp/dictation/>

²<http://htk.eng.cam.ac.uk/>

the Web corpus. The relevance score for document d is computed by Equation (2).

$$\sum_t f_{t,q} \cdot \frac{(K+1) \cdot f_{t,d}}{K \cdot \{(1-b) + \frac{dl_d}{b \cdot avgdl}\} + f_{t,d}} \cdot \log \frac{N - n_t + 0.5}{n_t + 0.5} \quad (2)$$

Here, $f_{t,q}$ and $f_{t,d}$ denote the frequency with which term t appears in query q and document d , respectively. N and n_t denote the total number of documents in the Web corpus and the number of documents containing term t , respectively. dl_p denotes the length of document d , and $avgdl$ denotes the average length of documents in the Web corpus. We empirically set $K = 2.0$ and $b = 0.8$, respectively. We use content words, such as nouns, extracted from transcribed documents as index terms, and perform word-based indexing. We use the ChaSen morphological analyzer³ to extract content words. The same method is used to extract terms from queries.

3. Experimentation

3.1. Methodology

To evaluate the effects of adaptation methods on speech recognition, we reused the test collection for our previous work [1]. Five lecture programs on TV, for which printed textbooks were also published, were videotaped in DV and were used as target lectures. Each lecture was transcribed manually and the sentence boundaries with temporal information were also identified manually.

Table 1 shows details of the five lectures. Each lecture was 45 minutes long. We shall use the term “word token” to refer to occurrences of words, and the term “word type” to refer to vocabulary items. The column “#Fillers” denoting the number of interjections in speech partially shows the fluency of each lecturer.

To evaluate the accuracy of speech recognition, we used the word error rate (WER), which is the ratio of the number of word errors (deletion, insertion, and substitution) to the total number of words. We also used test-set out-of-vocabulary rate (OOV) and trigram test-set perplexity (PP) to evaluate the extent to which our language model adapted to the target topics.

We used human transcriptions as test set data. For example, OOV is the ratio of the number of word tokens not contained in the language model for speech recognition to the total number of word tokens in the transcription. Note that smaller values of OOV, PP, and WER are obtained with better methods.

To adapt language models, we used the textbook for a target lecture and searched the 7M Web page corpus (see Section 2.2) for the N relevant pages, which were used as a source corpus. We set $N = 5000$, with which the best performance was obtained in a preliminary experiment. In the case where the language model adaptation was

not performed, all 7M pages were used as a source corpus. We used three different vocabulary sizes, i.e., 20K, 60K, and 100K. In either case, high frequency words in a source corpus were used to produce a word-based trigram language model. We used the ChaSen morphological analyzer to extract words from the source corpora, because Japanese sentences lack lexical segmentation.

For lecture #2 we did not perform acoustic model adaptation, because the speech data contained constant background noise and the sound quality was not good enough to adapt the acoustic model.

3.2. Results

Table 2 shows the values of OOV, PP, and WER for different methods. The columns “Base”, “+AM”, “+LM”, and “+AL” denote the results obtained by no adaptation, acoustic model adaptation, language model adaptation, and acoustic/language model adaptation, respectively.

Note that the values of OOV and PP do not change whether or not the acoustic model adaptation was performed. It should also be noted that because for lecture #2 the acoustic model adaptation was not performed, the values of WER for +AM and +AL are the same as those for Base and +LM, respectively.

Suggestions which can be derived from Table 2 are as follows. First, the values of OOV and PP decreased by language model adaptation, excepting lectures #2 and #3 with 20K and 60K vocabulary sizes.

Second, the values of WER generally decreased by adapting acoustic and language models, independently. The improvement obtained by each model was almost the same. However, when used together the improvement was even greater, resulting in the average value of WER was less than 40%. This result is encouraging because in the TREC spoken document retrieval track [7], the decrease of the retrieval accuracy was small if the value of WER was 30-40%.

Third, the values of WER decreased by adapting acoustic and language models even for the 60K and 100K vocabulary sizes, although in our previous study the vocabulary size was limited to 20K.

However, the values of WER themselves did not change significantly depending on the vocabulary size. One reason is that the average number of word types (i.e., the actual vocabulary size) in the 5,000 pages used to adapt a language model was approximately 54K, which was less than the permissible number. However, in the cases where we used all 7M pages, the vocabulary size was always the same as the permissible number.

Finally, by comparing the values of WER for 20K vocabulary size obtained with the adaptation (+AM, +LM, and +AL) and those for 60K and 100K vocabulary sizes obtained without the adaptation (Base), one can see that adapting the language model and/or the acoustic model was more effective than increasing the vocabulary size.

4. Conclusion

In this paper, to improve the quality of cross-media information retrieval system for lecture videos, we evaluated the effects of adapting acoustic and language models on speech recognition. We performed an MLLR-based method to adapt an acoustic model. To obtain a corpus for language model adaptation, we used the textbook for a target lecture to search a Web collection for the pages associated with the lecture topic. The experimental results for five lectures showed that the methods to adapt acoustic and language models improved the speech recognition accuracy independently and when used together the improvement was even greater.
